ABSTRACT

First reproduction report of *Trachemys scripta* in Portugal - Ria Formosa Natural Park, Algarve

We report the widespread occurrence of *Trachemys scripta* at Ria Formosa Natural Park, in sympatric conditions with native populations of *Emys orbicularis* and *Mauremys leprosa*, and the first confirmed case of successful reproduction in Portugal. The continuous naturalization reports of this invasive species, whose distribution has expanded worldwide in the last decades, confirm the need to implement urgent management measures for nature conservation, especially given the vulnerability of *Emys orbicularis* populations.

Key words: invasive species, Portugal, reproduction, *Trachemys scripta*

RESUMO

Primeiro relatório da reprodução de *Trachemys scripta* em Portugal – Parque Natural da Ria Formosa, Algarve

Neste trabalho apresenta-se evidências sobre a ocorrência generalizada de *Trachemys scripta* no Parque Natural da Ria Formosa, em condições simpátricas com populações nativas de *Emys orbicularis* e *Mauremys leprosa*, e o primeiro caso confirmado de reprodução com sucesso em Portugal. A contínua naturalização com sucesso desta espécie invasora, cuja sua distribuição tem vindo a aumentar por todo o mundo nas últimas décadas, confirma a necessidade de implementação de medidas de gestão urgentes para a conservação da natureza, especialmente dada a vulnerabilidade das populações de *Emys orbicularis*.

Palavras chave: espécies invasoras, Portugal, reprodução, *Trachemys scripta*

INTRODUCTION

The introduction of exotic species, and subsequent competitive interactions between these species and the native fauna, are identified as important drivers for global loss of biodiversity (Primack, 1997; Mooney *et al.*, 2005; Hulme *et al.*, 2009; Butchart *et al.*, 2010). The slider turtle, *Trachemys scripta*, native to the eastern and central United States of America, is considered one of the world's worst invasive alien species (Lowe *et al.*, 2000). The main cause of introduction into the wild stems from their massive trade as pets over the last decades, from turtle farms in the USA to foreign markets (Telecky, 2001). Until recently, they were legally sold in Europe as hatchlings (3-4 cm carapace length), and their owners are rarely prepared to maintain them in captivity when they start to grow (reaching up to 30 cm carapace length). This common situation leads to frequent releases of these animals in the wild, resulting in the introduction and establishment of many *T. scripta* populations into different natural freshwater ecosystems.

Currently this turtle has been reported as introduced into the wild outside its natural range throughout all continents: Europe (Luiselli *et al.*, 1997; Miranda & Leunda, 2010), Africa (Newberry, 1984), Asia (Chen & Lue, 1998), Oceania (Burgin, 2006) and America (Thomson *et al.*, 2010). Once introduced, the main requirement for its invasion is the occurrence of successful reproduction. Therefore, firm evidence about its reproduction is a key step towards understanding and managing its possible impacts on the invaded ecosystem (Herbold & Moyle, 1986). Nevertheless, during the last decade *T. scripta* has been confirmed to reproduce in several European countries, namely in different Mediterranean countries such as Italy (Ficetola *et al.*, 2003), France (Cadi *et al.*, 2004) and Spain (Pérez-Santigosa *et al.*, 2008).

In Europe, *T. scripta* has been reported to compete with native turtle species for basking places and food (Cadi & Joly, 2003; 2004; Pérez-Santigosa *et al.*, 2011). This situation is particularly alarming for the European pond turtle *Emys orbicularis*, which is considered as near threatened and in sharp decline in several regions

of its range (IUCN, 2014), and is therefore protected by European legislation (Cox & Temple, 2009) and subject of numerous conservation projects (e.g. Cadi & Miquet, 2004; Lacomba & Sancho, 2004; Ducotterd *et al.*, 2008; Schweitzer *et al.*, 2008; Fritz & Chiari, 2013; Teixeira *et al.*, 2013). In Portugal there are rising concerns about this species, since *E. orbicularis* is considered Endangered (Cabral *et al.*, 2005) and coexists with the native Mediterranean pond turtle *Mauremys leprosa*, which may increase their spatial segregation (Segurado & Figueiredo, 2007). So the early detection of *T. scripta* occurrence and the confirmation of its reproduction in new locations are key factors to the efficient development and implementation of adequate conservation measures and will contribute to raise the public awareness about this problematic situation.

In Portugal, at Ria Formosa Natural Park (PNRF) where *M. leprosa* and *E. orbicularis* populations coexist, *T. scripta* are sympatric. This area is populated with high densities of *M. leprosa* and contains one of the most important Portuguese populations of *E. orbicularis* (Cabral *et al.*, 2005), therefore, it has been implemented a conservation project in the region in this regard (LIFE Trachemys - LIFE09 NAT/ES/000529). Here we report the widespread occurrence at PNRF and the first confirmed case of successful reproduction of *T. scripta* in the wild, in Portugal.

MATERIALS AND METHODS

The Ria Formosa Natural Park (PNRF), located in the Algarve Region (South Portugal), is a protected area including a 60 km stretch of the Algarve coastline and occupies an area of about 18 400 hectares. Especially important because of its biological richness, it has the status of a Natural Park and is classified by the Ramsar Convention as a wetland of international interest.

From 2011 to 2013, between March and November, when the freshwater turtles activity is higher (Lebboroni & Chelazzi, 1991; Cadi & Joly, 2000), a set of permanent trapping techniques were implemented along four wetlands of special interest for the presence of *E. orbicularis* and *M. leprosa* populations: São

Lourenço (19.6 hectares), Quinta do Lago (1.5 hectares), Dunas Douradas (1 hectares) and Garrão (0.82 hectares), located along a 5 km coastal stretch in the Loulé council. The trapping techniques used were nine floating traps checked once a week, fourteen hoop traps checked every two days and hand nets whenever it was appropriate. All traps were distributed according to the size and shape of the water bodies, in order to evenly cover their entire area, giving six floating traps and six hoop traps at São Lourenço, two floating traps and three hoop traps at Quinta do Lago, one floating trap and three hoop traps at Dunas Douradas and two hoop traps at Garrão. The floating traps were placed in deeper areas where there were a greater number of individuals in thermoregulation or in areas with few supports for thermoregulation. The hoop traps were placed on the border of the water bodies in areas where the activity of individuals was higher and the trap could be conveniently hide. Adding to that, in order to evaluate the occurrence and abundance of *T. scripta* individuals throughout the PNRF area, visual surveys were performed every month, during the three years, around the main water bodies and streams along the Natural Park. Lastly, in July of 2013, an intensive search with a detection dog was conducted to detect nests around the São Lourenço wetland, where nesting

signs were higher. This dog was trained during the LIFE *Trachemys* project, with the help of a specialized dog trainer, to detect eggs, juveniles or adult *Trachemys specimens*.

All captured individuals were measured, weighed and numbered with a four numerical code, unique to each individual, which was placed on the marginal plates of the carapace through notches realized with a small saw. The carapace length and carapace width were measured using a caliper (precision: 0.1 mm) and the weight was recorded with a precision scale (precision: 0.1 g). All the invasive species individuals were identified following Ernst & Lovich, 2009 and LIFE *Trachemys*, 2012 and delivered on Official Reception Centers. Here, whenever evidence of eggs development were detected by inguinal palpation, females were radiographed. All *E. orbicularis* and *M. leprosa* individuals were immediately released at the capture site, after being given the individual code.

RESULTS

During the study period, we captured in the four wetlands where the trapping techniques were implemented a total of 259 individuals of different freshwater turtle invasive species, with 99 individuals being captured during the first year,

Figure 1. Total of distinct captured individuals per year from the different populations of invasive and native freshwater turtle species. Total de indivíduos distintos capturados por ano das diferentes populações de espécies invasoras e nativas de tartarugas-de-água-doce.

Figure 2. Total of captured individuals per year from the various invasive freshwater turtle species. *Total de indivíduos capturados por ano das várias espécies invasoras de tartarugas-de-água-doce.*

81 during the second year and 79 during the third year (Fig. 1). At the same time, we captured a total of 341 different individuals of *E. orbicularis* and 2286 of *M. leprosa*, with 156 *E. orbicularis* and 1487 *M. leprosa* being captured in the first year, 141 *E. orbicularis* and 531 *M. leprosa* in the second year and 44 *E. orbicularis* and 268 *M. leprosa* in the third year (Fig. 1). From all the captured invasive species individuals, 253 were from different sub-species of *T. scripta*, especially *T. s. elegans* (n=236), but also *T. s. scripta* (n=8), *T. s. troosti* (n=1) and hybrids between *T. s. elegans* and *T. s. scripta* (n=8) (Fig. 2). The remaining individuals were *Pseudemys concinna* (n=3), *Pseudemys nelsoni* (n=2) and *Graptemys pseudogeographica* (n=1) (Fig. 2). Overall, from the captured sample, most individuals were breeding adults, especially females, together with a high number of juveniles and some hatchlings (Table 1). All hatchlings had the umbilical scar on the middle of their plastron and none had growing rings on the carapace. Among all the adult females captured, 11 *T. s. elegans* were egg-bearing females, identified by palpation, including one that was already covering the nest, near the border of São Lourenço wetland. The nest

contained 15 *T. s. elegans* eggs that we removed to prevent their future hatchling. For all the other 10 females, the X-rays revealed 17 eggs on average (minimum 15/maximum 21).

The surveys performed throughout all the Natural Park area confirmed the permanent presence of *T. scripta* populations scattered all over the Natural Park during the three years and all the estimates of observed individuals indicated the constant occurrence of hundreds of individuals (adults and juveniles) each year.

The detection dog was used for testing 4 sites, identified as more suitable for nesting near the border of São Lourenço wetland, in a total of approximately 2 hectares, with 2 visits of 1 hour/per site. One nest of *T. s. elegans* was detected, at the same area where most of the newly hatched nests and a female nesting during the spring were already encountered. The nest contained 14 eggs with newly hatched *T. s. elegans* and some still hatching, that we also removed immediately.

DISCUSSION

Our study showed that *T. scripta* occurs in high densities in the study area and confirmed for the first time the reproduction of this species in Portugal. The high number of captured and removed individuals from natural conditions, repeatedly over the three years of study, reveals an established population and the occurrence of

Table 1. Characterization of the population sample of freshwater turtle invasive species captured. constant recruitment from the surroundings. The results of the surveys performed throughout the three years on the study area, support the idea of a wider distribution of the population that can provide the conditions for a successful naturalization. Adding to that, the high number of captured hatchlings, still with the presence of umbilical scar and absence of growing rings, suggest the existence of successful reproduction, since they all are smaller than the mean for *T. scripta* hatchlings described by Janzen *et al.* (2000). Furthermore, hundreds of individuals of both gender and different ages captured and observed throughout the PNRF, as well as the several adult egg-bearing females encountered near nesting sites, support the idea that they were able to adapt to the natural conditions and to establish successfully. This situation increases the direct competition with native turtles, adding a new disturbance factor and increasingly restricting the places where they occur naturally and the invasion process has not occurred yet. Lastly, the use of a detection dog for reproduction evidence, even it has not been used extensively, showed certain success, giving the location of one nest that provided evidence of reproduction of *T. scripta* and confirmed the promising application of this technique, initially developed in Australia by the Queensland Department of Natural Resources (O'Keeffe, 2005).

These results are alarming and represent a viable invasive population, co-occurring with important native populations of *E. orbicularis*. Without an intensive control and population management, this situation can lead to a massive and widespread naturalization of this species, with irreversible negative impacts on native fauna and on the ecosystem functioning, similarly to what has been observed in other areas throughout Europe (Cadi *et al.*, 2004; Pérez-Santigosa *et al.*, 2008).

Although *T. scripta* is very common and popular as a pet, its invasive status and impact on local ecosystems and native species are still unknown for the general public. The evidence of successful reproduction and establishment by this species in the study area might be a first sign to help rising public awareness for this problem.

Together with the successful reproduction reports of *T. scripta* in Spain (Martinez-Silvestre

et al., 1997), Italy (Ficetola *et al.*, 2003) and France (Cadi *et al.*, 2004), the confirmed reproduction of *T. scripta* at Ria Formosa Natural Park in Portugal reinforces the possibility of permanent establishment of this species within all the Mediterranean region. This data enhances the urgent need to strengthen the European legislation, banning the trade of all *T. scripta* subspecies, trade control and population management by promoting an European Invasion Alert Network and early eradication campaigns from natural wetlands.

ACKNOWLEDGMENTS

This research was supported by the LIFE Trachemys project (LIFE09 NAT/ES/000529). We thank DogAlgarve, especially the dog trainer Américo Lopes and everyone who helped in the fieldwork, especially Thijs Valkenburg, Tiago Ventura, Mauro Hilário, Jael Palhas and António Cotão.
